THE ART OF SCREENING: EFFECTIVENESS OF SILT SCREENS

ABSTRACT

One of the potential environmental issues associated with dredging in the marine environment is the increase of suspended sediment concentrations (SSC) by generation and dispersion of sediment plumes. This can be mitigated by source control or by the installation of containment barriers like silt screens. This article focusses on hanging silt screens and describes:

1. The decision process for deployment of hanging silt screens: Decisions on the necessity of environmental mitigation measures and subsequently on the viability of silt screen deployment should be made using a receptor-based approach. This starts with the identification of (ecological) receptors and related impact levels, understanding the local environment, checking compatibility with work methods and determining cost and schedule impacts.

2. Effectiveness of hanging silt screens: Local hydrodynamic and morphological circumstances determine the effectiveness of silt screens. Results of extensive numerical modeling tests (3D and 2DH) supported by hands-on experiences from dredging projects are used to describe the effect of hanging silt screens on the distribution of SSC in the water under different conditions. Results show that when deploying silt screens it is important to realise that silt screens are flexible curtains; they do not block the flow. Therefore suspended sediments generated at a dredging project will always pass the hanging screen vertically and/or horizontally. Silt screens can only reduce the distribution of SSC by settling if local hydrodynamic conditions are favourable.

3. Adaptive management strategies as an alternative for silt screens: When local conditions are not optimal for deployment of silt screens, alternative mitigation measure, such as adaptive monitoring strategies, can be used to manage SSC around dredging projects.

Mr Radermacher gratefully acknowledges his co-authors Fokko van der Goot, Project Engineer and Daan Rijks, Senior Project Engineer, both at Royal Boskalis Westminster and Lynyrd de Wit, Project Engineer, Svasek Hydraulics for their collaboration on this study. This article appeared in the Proceedings of WODCON XX, Brussels, Belgium, June 2013 and is published here in a slightly adapted version with the permission of the World Organization of Dredging Associations (WODA).

Nomenclature

- $C$ = Suspended sediment concentration [kg/m$^3$]
- $C_{max}$ = Maximum $C$ in upstream domain [kg/m$^3$]
- $C_*$ = Dimensionless $C$ [-]
- $E_{in}$ = Inflow effectiveness [%]
- $E_{ref}$ = Reference effectiveness [%]
- $Fr$ = Froude number [-]
- $P$ = Environmental impact potential [-]
- $Q_{rel}$ = Relative discharge [-]
- $U$ = Depth-averaged flow velocity [m/s]
- $W_s$ = Silt screen width [m]
- $W_{s,ref}$ = Dimensionless silt screen width [-]
- $g$ = Gravitational acceleration [m/s$^2$]
- $h$ = Water depth [m]
- $h_{s,rel}$ = Relative silt screen height [-]
- $h_s$ = Silt screen height [m]
- $w_s$ = Settling velocity [m/s]
- $z_*$ = Dimensionless z-coordinate [-]
- $\theta$ = Velocity ratio [-]
INTRODUCTION

In the past years, dredging contractors have gained extensive experience in the realisation of marine infrastructure projects in environmentally sensitive areas and in related monitoring of the environmental effects resulting from the construction activities themselves. One of these potential environmental effects is the generation and dispersion of suspended sediments during dredging and associated marine construction activities.

In an effort to minimise possible impacts of suspended sediments on sensitive receptors such as coral reefs, project and permit requirements are increasingly asking for the implementation of specific measures such as silt screens, even though local project conditions ensure that effectiveness of deployment is questionable.

Silt screens are flexible barriers that (partly) block current flows containing increased suspended sediment concentrations (SSC). Typically, two types of silt screens are used:

– hanging silt screens that aim to promote downward migration of suspended sediments to a deeper level in the water column to allow for a shorter settling time, and
– standing silt screens which are connected to the seabed by a heavy weight (e.g., immersed pipeline) and kept in vertical position by means of surface floaters (Figure 1).

Generally, hanging silt screens are applied most often as they require less stringent mechanical restrictions and are easier to deploy and maintain.

Silt screens have been subject to research for a few decades. Mechanical and practical aspects have been treated extensively (JBF Scientific Corporation, 1978; Francingués and Palermo, 2005; Ogilvie et al., 2012). Assessments of silt screen effectiveness regarding mitigation of environmental impact have also been made based on measurements in the field and laboratory experiments (Yasui et al., 1999; Jin et al., 2003; Vu et al., 2010; Vu and Tan, 2010).

Despite all these publications, detailed and rigid conclusions on silt screen performance have not been drawn yet. For that purpose, systematic research is needed to supplement results of (incidental) stand-alone field experiments in order to relate the research outcomes to engineering practice. This article presents an integral view on the viability of silt screen application in the field based on extensive modelling results (Radermacher, 2013) in combination with hands-on field experience.

The first part of the article provides an overview of the decision-making process on silt screen deployment from an environmental and operational point of view. Subsequently, the design of reliable and effective silt screens is studied in detail based on operational trials, flume tests and numerical modelling (3D and 2DH) and supported by experiences from dredging projects. Finally, the article suggests alternative measures, including adaptive monitoring strategies, that can be used to manage SSC around dredging projects if silt screens are proved not to be effective.

DECISION PROCESS: WHEN TO APPLY SILT SCREENS?

Temporary effects of dredging refer to the increase in turbidity as a result of the release of suspended sediments into the water column during the dredging process. Decisions on deployment of silt screens to mitigate these impacts ideally go through the following three steps, effectively using a receptor-based approach:

1. determine the necessity of environmental mitigation measures;
2. determine the viability of silt screen application;
3. installation and operability of a silt screen.

Determine the necessity of environmental mitigation measures

It is important to realise that turbidity occurs naturally and that species of flora and fauna can cope with variances in turbidity levels and in some cases will not be affected by fluctuations resulting from project operations. Furthermore, (natural) sediment plumes can be important for the health of some ecosystems as a source of nutrients (organic matter). In most cases, however, a non-natural increase in turbidity level over an extended period of time has a negative impact on the surrounding environment.

When determining background turbidity values, the natural processes such as river peak discharges and re-suspension of fine sediments during storms need to be taken into account as well as other human-induced activities such as fishing and ship-maneuvering operations (Aarninkhof et al., 2008).

Once the background values and fluctuations are known, the severity and spatial extent of the project-related sediment plumes and associated potential environmental impact can be determined including the necessity of mitigation measures (see, for example, PIANC, 2010):

– determine presence and type of sensitive receptors relative to dredging/disposal operations, the detectable stress-response of these receptors and the timing (e.g., in relation to coral spawning periods) concerning duration and frequency of the sediment plume;
– determine existing receptor stress levels in combination with the local background conditions regarding, e.g., turbidity levels.
resulting from natural processes and other human-induced activities;
– estimate/model the transport of suspended sediment within a plume based on local water depth, hydrodynamic conditions (e.g., tidal/seasonal currents) and sediment characteristics (e.g., settling behaviour); and
– investigate the character of the dredging/disposal operations (e.g., type of equipment, production rate) in combination with the character of the dredged/disposed material (e.g., fines content, in-situ density) as both determine the type and magnitude of the source of a sediment plume.

From the above list, the need for, and type of, environmental mitigation measure clearly has to be determined for every project individually, based on thorough understanding of the local environment. Providing “typical impacts” of dredging operations is very difficult, as these depend on the type of activity, work method and equipment, distance from activity, ambient flow characteristics and particle characteristics (e.g., settling of suspended sediments). Therefore, a fit-for-purpose solution needs to be found based on both the environment and the dredging work method to ensure maximum efficacy of a suggested mitigation measure such as a silt screen.

**Determine the viability of silt screen application**

In present day dredging practice, silt screens are often regarded as the ideal answer to dredging-induced SSC. Admittedly, silt screens have many advantages over alternative mitigation measures in terms of operational implications, production and costs. However, absolute effectiveness of the silt screen regarding reduction of environmental impact should always be taken into account and be a necessary condition to proceed to silt screen placement.

**Application of hanging or standing silt screens**

Silt screens generally come in two different types – hanging and standing – which in turn can be applied in a number of different configurations (JBF Scientific Corporation, 1978; Francingues and Palermo, 2005; Ogilvie et al., 2012). The choice of screen and configuration type depends on a combination of local hydraulic conditions, the source of suspended sediments and operational demands. Of these three, the local hydraulic conditions are the main limiting factor to the viability of silt screen application, both in terms of constructional failure and failure from an environmental point of view.

Mechanical aspects of silt screens in an open configuration have been treated extensively in literature, leading to the conclusion that hanging silt screens get damaged easily when current velocities exceed 0.5 to 0.8 m/s (Francingues and Palermo, 2005). Explicit limiting values regarding mechanical failure of silt screens of the standing type do not occur in literature. As a result of their full coverage of the water column, standing silt screens have to cope with much higher hydraulic loads than hanging silt screens. Hence the application of standing silt screens in an open configuration is limited to very mild hydraulic conditions and geometries which allow weak currents to pass around the screen’s side edges. Similar limitations apply to silt screens in a closed configuration.

**Viability with regards to sources of suspended sediments**

Sources of suspended sediment may occur throughout the complete dredging cycle of dislodging, transport and placement of bed material. Depending on the activity causing dredged material to get suspended in ambient water, initially the transport of suspended sediment can be density-driven (i.e., dynamic plumes, mostly occurring in the placement stage) or dominated by turbulent mixing in the main flow (i.e., passive plumes). At some distance from the source, dynamic plumes either settle out or proceed as passive plumes.

Hanging silt screens are typically intended to mitigate passive plumes, as they have a distinctly negative effect on dynamic plumes (JBF Scientific Corporation, 1978; Radermacher, 2013). As a result, they should be applied at some distance from dredging activities which involve dynamic plumes. Standing silt screens in turn effectively block near-bed propagation of dynamic plumes.

**Installation and operability of a silt screen**

Silt screen usage in dredging projects has a (large) operational impact. Most hanging silt screens available on the market are not
designed for efficient use in dredging and marine construction projects. Traditional mooring systems require an extreme quantity of anchors. This is unpractical when located in the vicinity of dredging works (interference of anchors and anchor lines with works) or when frequent relocation of the silt screen is required. From an operational point of view, the combination of a robust construction and a substantial reduction of anchoring points is the safest, least expensive and most operationally desirable choice.

When considering hanging or standing screens, experience has proven that the operability of a standing silt screen is limited as a result of its fixation on the seabed. Deployment, maintenance and re-positioning of the screen require more effort in comparison to handling hanging silt screens. Furthermore, the standing screens risk being partly buried by the blocked and subsequently settled sediment. From an operational point of view, hanging silt screens are preferred.

During the installation and operation of a silt screen, the following aspects have to be considered in order to achieve sufficient protection and durability of the silt screen system:

- the availability of sufficient area to assemble the silt screens on shore (see opening photo);
- the presence of spare silt screens to allow quick replacement of damaged silt screens;
- a technical solution which allows the dredging and auxiliary equipment to move in and out of the shielded area; and
- the permanent availability of a support vessel, such as a multicat or multipurpose vessel, to assist in the installation and repositioning of the screen if required.

Following the above, deployment of silt screens at a dredging project have a major impact on the project organisation and costs, especially when requirements state that the dredging site needs to be fully enclosed with silt screens.

**EFFECTIVENESS OF SILT SCREENS**

From the previous section it has become clear that silt screens of the standing type and silt screens in closed formation can only be applied effectively under very mild conditions, mainly as a result of local hydrodynamic considerations. However, performance of *hanging* silt screens in an open formation, as often applied in present-day dredging practice, is questionable. The open character allows currents to pass more easily, which results in lower hydraulic loading, but also in the passage of suspended sediments. The remainder of this section will focus on the effectiveness of hanging silt screens in an open configuration (Radermacher, 2013).

**Current flows around silt screens**

Analysis of mechanisms that account for passage of suspended sediment laden currents around silt screens leaves two key processes (see Figure 2):

- **Vertical diversion**

  Vertical diversion occurs in case of a hanging silt screen in cross-flow, as hydraulic loading causes the flexible screen to flare. Even in the case that the screen height is equal to the water depth, a significant gap will open near the bed. Horizontal diversion is only possible if there are no lateral restrictions (e.g., quay walls, bunds) and therefore mainly applies to silt screens in open water.

- **Horizontal diversion**

  Horizontal diversion is investigated by means of a 2-dimensional horizontal (2DH) model approach, in which the silt screen is schematised as a discharge relation at a series of internal grid cell edges.

Further analysis of these two processes is done consecutively in the next two sections. Vertical diversion is investigated by means of 3-dimensional numerical model simulations, making use of Large Eddy Simulation (LES) to account for turbulence closure. Validation data are obtained from laboratory experiments. Horizontal diversion is investigated by means of a 2-dimensional horizontal (2DH) model approach, in which the silt screen is schematised as a discharge relation at a series of internal grid cell edges.

**Vertical diversion of flow**

Hanging silt screens are intended to promote quick settling of suspended sediments by bringing particles close to the bed (vertical diversion) thereby lowering the extent of the environmental impact.

In order to quantify the effectiveness of a silt screen, the study introduces an environmental impact potential $P$. A silt screen is considered to be effective whenever it is able to reduce $P$. 

![Diagram of current flows around a hanging silt screen](image)
P is given by the product of the SSC and the vertical level above the bed:

\[ P = \int_0^1 C_z \, dz \cdot \]  
with \( C_z = \frac{C}{C_{\text{max}}} \)

\[ z_s = \frac{z}{h} \]

\( C_{\text{max}} \) denotes the maximum SSC value upstream of the silt screen and \( h \) denotes water depth. It is chosen to use a linear relation between \( C_z \) and \( z_s \), because the potential environmental impact often scales linearly with SSC and the potential impact time of the sediment particles scales linearly with their vertical distance from the bed.

The study expresses the effectiveness of silt screens as a percentage of reduction of \( P \) achieved by the screen. The reference value of this reduction is still to be determined. Many authors have suggested the use of a value upstream (also referred to as inside) of the silt screen (JBF Scientific Corporation, 1978; Francingues and Palermo, 2005; Vu et al., 2010; Ogilvie et al., 2012). Note that these authors use \( C \) instead of \( P \) to compute the effectiveness. This type of effectiveness parameter is coined the inflow effectiveness \( E_{\text{in}} \) here.

Despite the widespread usage of \( E_{\text{in}} \) as a measure for silt screen effectiveness, a second parameter is introduced here. A silt screen has to achieve a significant reduction of \( P \). In fact, it is argued here that it should lead to improvement with respect to the reference situation of the same sediment plume in a configuration without silt screen. Effectiveness with respect to the reference situation is coined the reference effectiveness \( E_{\text{ref}} \).

The difference with \( E_{\text{in}} \) lies in the influence of (autonomous) settling of sediment in between the upstream and downstream locations (Figure 3). For very fine particles the difference will be negligible, but if the particle size increases, the difference between both parameters will grow ever bigger. The definitions of \( E_{\text{in}} \) and \( E_{\text{ref}} \) are given in equation [2].

\[ E_{\text{in}} = \frac{P_{\text{in}} - P(x)}{P_{\text{in}}} \cdot 100\% \]
\[ E_{\text{ref}} = \frac{P_{\text{ref}}(x) - P(x)}{P_{\text{in}}} \cdot 100\% \]

In the study, a large number of numerical model simulations were conducted in order to chart the effectiveness of silt screens as a function of depth-averaged horizontal flow velocity \( U \), silt screen height \( h_{\text{rel}} \), settling velocity \( w_s \), and the upstream vertical profile of SSC. The water depth is kept fixed, as \( h \) only influences the effectiveness of silt screens through the relative silt screen height \( h_{\text{rel}} \), being the ratio of \( h \) over \( h \). The model domain is depicted in Figure 4.

To arrive at a compact and generic representation of the model results, every simulation is characterised by means of two dimensionless groups: the velocity ratio \( \theta \) and the relative screen height \( h_{\text{rel}} \) as shown in equation [3].

\[ \theta = \frac{w_s}{U} \]
\[ h_{\text{rel}} = \frac{h_s}{h} \]

The velocity ratio \( \theta \) can be regarded as a parameter indicating the favourability of settling conditions. The higher \( \theta \), the shorter the horizontal settling distance of suspended sediment. Relative screen height \( h_{\text{rel}} \) represents two aspects: the initial vertical displacement of suspended sediment and the amount of flow disturbance caused by the silt screen.

For each combination of effectiveness parameter \( (E_{\text{in}} \text{ or } E_{\text{ref}}) \), upstream SSC profile and downstream x-coordinate, the effectiveness of silt screens is displayed in the \( \theta \)-\( h_{\text{rel}} \) plane. As an example, the inflow effectiveness is treated for a uniform upstream SSC profile (uniform value over the full water column) at 6 times the water depth downstream of the silt screen. This is shown in Figure 5.

The triangular markers in Figure 5 indicate actually obtained data points. Contour lines of equal \( E_{\text{in}} \) are constructed from interpolation.

Figure 5 shows a maximum positive \( E_{\text{in}} \) of 90%. The most positive \( E_{\text{in}} \) is obtained for large values of \( \theta \), which corresponds to large settling velocities. Above \( \theta = 5 \cdot 10^{-2} \) (e.g. \( w_s = 2 \text{ mm/s} \), \( U = 4 \text{ cm/s} \)), the reduction of \( P \) with respect to the upstream value becomes significant. For small \( \theta \) values (small settling velocities) the silt screen is not positive, but also not negative: \( E_{\text{in}} = 0\% \). There is only a very weak relation between \( h_{\text{rel}} \) and \( E_{\text{in}} \); for larger \( h_{\text{rel}} \) \( E_{\text{in}} \) is slightly less. This can be explained by the increased mixing for a larger vertical screen; increased mixing leads to a spreading of SSC to higher z-coordinates, which gives rise to a high environmental impact potential \( P \).

Subsequently, the reference effectiveness \( E_{\text{ref}} \) is evaluated for the same parameters: At 6 times...
the water depth downstream and with a uniform upstream SSC profile (Figure 6). The difference between Figure 5 with $E_{in}$ and Figure 6 with $E_{ref}$ is clear: Although $E_{in}$ showed positive effectiveness of the silt screen in the range of realistic $h_{rel}$ and $\theta$, $E_{ref}$ is never positive in the same range of $h_{rel}$ and $\theta$.

When settling conditions become favourable (i.e., at high $\theta$), the autonomous settling of suspended particles in a reference situation without a silt screen is more than the settling in case of a silt screen. Therefore $E_{ref}$ is negative for larger $\theta$. For low $\theta$, $E_{ref}$ attains values close to 0%, but $E_{ref}$ never becomes significantly positive.

This means that for all realistic $\theta$ and $h_{rel}$, applying no silt screen at all is better. Although the silt screen reduces $P$ compared to upstream (it causes a positive $E_{in}$ in Figure 5), Figure 6 makes clear that the reduction of $P$ would have been even more without a silt screen (never a positive $E_{ref}$ in Figure 6). This direct comparison of $E_{in}$ and $E_{ref}$ makes it clear that $E_{ref}$ is the better parameter to judge the effectiveness of a silt screen, even though it is harder to determine in the field on a dredging site than $E_{in}$.

With different upstream concentration profiles, the effectiveness contours in the $\theta$-$h_{rel}$ plane show different patterns. Generally two different types can be distinguished: Profiles with the biggest sediment load in the lower part of the water column and profiles with the biggest sediment load in the upper part of the water column. In the former case the vertical mixing caused by the silt screen can only do damage: the sediment load was already at its most favourable position close to the bed. But even in the latter case, with an upstream sediment load in the upper part of the water column, the $E_{ref}$ effectiveness never exceeds 10%. Given all the costs and effort needed to place silt screens, a maximum positive effectiveness of only 10% is considered to be too low to apply a silt screen. Even though so far only a continuous supply of SSC upstream of the silt screen has been considered, no positive $E_{ref}$ is obtained for discontinuous supplies either (Radermacher, 2013).

Note: Flow contraction underneath a silt screen can induce a submerged jet flow near the bed. If erodible bed material is available, the high velocities occurring in this jet flow give rise to enhanced erosion and suspended sediments. This additional effect has not been accounted for in the analysis above and, depending on local conditions, might lead to even lower effectiveness percentages.

**Horizontal diversion of flow**

Despite the considerations presented in the previous section, vertical diversion is in fact the intended effect of hanging silt screens, as it is thought to bring SSC closer to the bed. However, the presence of a silt screen also induces a big resistance to horizontal flow which will naturally follow the path of least resistance. This means that a part of the incoming current will be diverted in the horizontal plane and pass the screen around its side edges if lateral restrictions are absent (Figure 7).

This counteracts the intended usage of silt screens as a vertical current deflector and is therefore an unwanted effect. The amount of horizontal diversion can be quantified by defining the relative discharge $Q_{rel}$. It denotes the ratio of the discharge passing underneath the screen’s lower edge and the total upstream discharge over the full width of the silt screen $= Q_{rel}/Q_{tot} \times 100\%$. It thus represents the percentage of vertical diversion. Hence the percentage of horizontal diversion is equal to $100\%-Q_{rel}$.
40% of the incoming discharge is diverted vertically. The remaining 60% passes the silt screen around its side edges.

In summary, a silt screen of finite width will give rise to horizontal diversion of sediment-laden flow if lateral restrictions are absent. Hence a dredging plume will partly pass the screen around its side edges, which allows for free spreading of suspended sediment. Using horizontal diversion as a beneficial process, i.e., trying to guide the current away from potential sensitive receptors, has been proved to be counterproductive (Radermacher, 2013).

**EXPERIENCE FROM SILT SCREEN APPLICATION IN THE FIELD**

The results of the modelling and lab tests described above are supported by observations and experiences obtained during the execution and monitoring of various projects in the field. In fact, based on evaluations of a range of dredging projects in the Arabian Gulf, Caribbean and Pacific Ocean where different silt screen set ups have been applied, the following prerequisites for successful use of hanging silt screens were determined.
the seabed. The local flow field around the silt screen causes additional stirring of fine sediments into the water column. As a result, plume decay times increase.

Dedicated field experiments at a dredging project in the Arabian Gulf have shown that, for very specific applications, silt screens are an effective measure to mitigate dredging-induced turbidity levels. These applications include sheltered reclamations in enclosed basins (SSC decrease to 25-40% of original level) and the unloading of barges through open bottom doors (SSC decrease to 20-25% of original level). However, it should be noted that charting the flow field in full detail from field measurements is not possible. The effectiveness percentages have been determined from comparison of single point measurements of turbidity values (instead of P) on both sides of the silt screen ('inflow' type of effectiveness parameter instead of 'reference' type).

ADAPTIVE MANAGEMENT STRATEGIES AS AN ALTERNATIVE TO SILT SCREENS

The use of silt screens is in fact a mitigation measure specifically aimed at reducing sediments already in suspension. As has been described in detail above, only a limited number of local environmental circumstances and/or dredging and construction work methods allow for effective deployment of silt screens.
In many cases determining measures that focus on source control and specifically on minimising the actual generation of suspended sediments into the water column is more effective. This can be done by designing smart dredging and construction procedures supported by verification monitoring and modelling programs, so-called adaptive management strategies. This will allow for effective SSC management and reduction of related environmental impacts.

The aim of adaptive management (see Figure 12) is to improve the specific project's environmental management through “learning by doing” and using feedback to adjust construction operations to better meet the project objectives (functional requirements and environmental objectives [PIANC, 2009]). Adaptive management is incorporated in the design of the dredging operation work methods and comprises a combination of proactive and responsive measures.

Proactive management measures aim to optimise the design of the work method in terms of limiting potential environmental impacts of the dredging, both on the short-term (same temporal scale as the dredging execution period) and longer term. Responsive management involves the continuous incorporation of new information and lessons learned (e.g., monitoring data, project

**Receptor-based approach**

1. **Understanding the local**
2. **Forecast modelling**
3. **Field monitoring**
4. **Feedback monitoring**
5. **Design / Apply / Adapt mitigation measures**

---

Figure 10. A hanging silt screen at a dredging project in the Arabian Gulf at a reclamation discharge was applied successfully in combination with a breakwater and minimal current velocity.

Figure 11. A silt screen application at a dredging project in the Caribbean with reversed effect caused by natural variation in suspended sediments as a result of a nearby river discharge (courtesy of Kent Reid).

Figure 12. An adaptive management strategy.
This strategy enables the project team to:
- fully understand and control the transportation and fate of fine sediments around dredging operations;
- adopt an early warning response mechanism to potential exceedance of environmental limits;
- test environmental compliance of future dredging/disposal scenarios; and
- design appropriate contingency measures.

In many cases, this adaptive management strategy is more effective than simply applying generic mitigation measures such as silt curtains as it focuses on reducing the suspended sediments at the source. However, when implementing an adaptive management strategy, the following considerations should be taken into account:
- Adapting dredging procedures could have serious implications for the production rates, progress of work and often involve additional costs.
- Adaptive management is more cost-effective when applied at more complex dredging projects lasting for at least several months or longer.
- Besides optimising dredging procedures, adaptive management involves verification of effectiveness of the measures taken. Verification methods could include a combination of baseline sediment and marine habitat monitoring, feedback monitoring and hindcast and forecast sediment modelling.
- Adaptive management should be an integral part of project preparation to avoid unforeseen delays and costs.

### CONCLUSIONS

This article aims to treat the effectiveness of silt screens in an integral way. Main insights on silt screen effectiveness are:
- Hanging silt screens in an open configuration do not achieve a significantly positive performance in mitigating the potential environmental impact of suspended sediment, regardless of local flow conditions and silt screen geometry.
- Silt screen effectiveness must be rated with a reference effectiveness parameter (comparing the situation with and without silt screen), not with an inflow effectiveness parameter (comparing downstream with upstream of the silt screen) as has always been done up to now.
- Hanging silt screens often have a positive inflow effectiveness, but this study shows that in the case of a current, even with a positive inflow effectiveness, it would have been better to have no hanging silt screen at all: The reference effectiveness is not positive.
- Flow contraction underneath hanging silt screens actually leads to enhanced erosion if erodible bed material is available.
- Silt screens in an open configuration give rise to a significant amount of horizontal flow diversion, which counteracts the intended use of silt screens as a vertical current deflector.
- Adaptive management strategies are a viable alternative to the application of silt screens.

The conclusion of this study is that hanging silt screens in an open configuration, as often applied in present-day dredging practice, are not effective in reducing the environmental impact of dredging projects.

The recommendation is to integrate the insights about silt screen effectiveness as described here in the decision making process regarding mitigation of potential environmental impact of suspended sediments, using a receptor-based approach and adaptive management strategies. Relying solely on silt screens, even when local conditions ensure that their effectiveness is negligible (or even adverse), hinders progress in the protection of the marine environment.
